The effects of long-term (213.0 ± 30.5 days) aboard the Mir station and short-term (~10 days) spaceflights aboard the International Space Station (ISS) on the joint torques of various muscles and work capacity of knee extensors were studied in male cosmonauts. Joint torque and muscle endurance testing was performed 30 days before and 3–5 days after a spaceflight, using a LIDO® Multi-Joint Isokinetic Rehabilitation System (USA). Greater postflight changes in maximal joint torque were observed for back, knee, and ankle extensors compared with flexors, and the difference was especially clearly seen after long-term spaceflights. Muscle work capacity was inferred from the gradient of declining muscle force produced in a series of rhythmic voluntary concentric movements and was found to decrease after both short- and long-term spaceflights. The area under the muscle contraction curve decreased to a greater extent and in all regions of the curve after long-term spaceflights. The finding that the contractile functions and work capacity of muscles decrease more after long-term than after short-term spaceflights in spite of the physical training program of a certain type gave grounds to assume that physical training employed in long-term spaceflights were insufficient to simulate the daily mechanical load that the cosmonauts had before a spaceflight.

Key words: real microgravity, spaceflight, contractile properties, isokinetic dynamometry
INTRODUCTION

A microgravity due to actual (spaceflight) or simulated microgravity (bed rest, immersion, or unilateral lower limb unloading) provides a unique environment where forces of body interactions with a support are absent, causing physiologically adverse problems to various body systems and, in particular, the locomotor system. Extremely complex changes arise in muscle mass, and contractile function in microgravity in spite of physical training (PT) employed during long-term spaceflights, as has been demonstrated in many studies. The loss of skeletal muscle mass [46] and concomitant changes in muscle function [66] induced by prolonged sojourns in microgravity environments can adversely affect the performance of astronauts during routine mission-related activities and upon their return to Earth.

Muscle mass loss of 4–10 % has been observed in astronauts after an 8-day Shuttle mission [47]. The muscle volume has been reported to decrease to a somewhat greater extent, by 6–16 %, with the spaceflight duration increasing from 9 to 16 days [2]. Moreover, muscle fiber atrophy of 16–36 % has been found in m. vastus lateralis after an 11-day spaceflight [16].

Greater losses of muscle mass occur during longer spaceflights in spite of employing PT programs. For instance, a decrease of 10–24 % in muscle volume has been observed in astronauts after missions of approximately 6 month to the Mir space station and the International Space Station (ISS) [18, 46, 56, 67]. However, the muscle mass has been found to stabilize to a certain extent or to achieve a new stable level in humans exposed to 120-day antiorthostatic bed rest [46], which is used as a main ground-based model of long-term spaceflights to study the long-term effects of microgravity [18].

The strength of muscle contraction decreases in parallel with muscle volume loss, but the changes in strength are somewhat greater [4, 5, 9, 14, 28, 45]. For instance, a substantial (up to 14 %) decrease in hand muscle contraction strength has been observed after short-term (2–5 days) spaceflights aboard Soyuz spacecrafts [27], and decreases of 12 % in the strength of hip extensors, 23 % in the strength of hip flexors [10, 20], and up to 16 % in muscle work capacity [2, 47, 46, 56, 64] have been reported for astronauts after Shuttle missions of 5–17 days.

Studies of the force–velocity characteristics of ankle extensors and flexors by conventional isokinetic dynamometry after a 7-day spaceflight have shown a decrease in the strength of ankle extensors throughout the velocity range examined, including an isokinetic regimen, the decrease amounting to 20–30 % of the baseline in all but the isometric mode and being somewhat lower, ~ 15 %, in the isometric regimen [22, 39, 42].

Postflight measurements in crew members after missions of 16–28 weeks to the Mir space station have shown a decrease of up to 48 % in the force of maximal voluntary contraction (MVC) of ankle flexors [66] an a 31 % increase in the maximal shortening velocity of muscle fibers [44]. The contraction force of knee extensors and the endurance of knee flexors have been found to decrease by approximately 26 % after a mission of 129–145 days to the ISS [48]. Trappe et al. [66] have reported decreases in maximal power (by 32 %) and maximal force (by 20–29 %) of ankle
extensors in voluntary movements in a broad isokinetic velocity range after a mission of approximately 6 month to the ISS [66]. It is commonly accepted that major losses affect trunk and lower limb muscles, which are highly active under normal Earth’s gravity (1 g). Muscle strength in the upper limbs is affected to a lesser extent than that in the lower limbs [13, 22].

The fact that losses in muscle strength are greater than losses in muscle mass (volume) after both spaceflight s and model exposures (immersion, bed rest, or limb suspension) has prompted a hypothesis that the motor control is basically affected in microgravity [1, 37, 40]. For instance, a 45 % decrease in power produced by hip extensors after a 180-day spaceflight is considerably greater than can be explained solely by muscle mass loss [40]. A decrease in power produced by hip extensors during explosive voluntary contractions is accompanied by a substantial decrease in their electromyographic (EMG) activity [40]. Zange et al. [67] have observed a greater percent change in force (by 20–48%) than in muscle volume (by 6–20 %) for knee extensor by magnetic resonance imaging. Lambertz et al. [44] have similarly reported a 17 % decrease in isometric force after 90–180 days.

A decrease in muscle contraction force has been accompanied by a decrease in EMG activity of ankle extensors, averaging 39 % [44]. Concomitant changes observed after spaceflights have similarly been detected in ground-based model studies simulating muscle unloading. For instance, Hather et al. [26] have shown using MRI that a 6-week unilateral unloading of the left leg reduced the cross-sectional area (CSA) of its hip extensors by 12 % relative to the right leg, which was not unloaded. The total muscle CSA of the left leg was 14 % lower than that of the right leg. MRI showed irregular reduction of the CSA for thigh muscles. The CSA reduction in hip extensors (–16 %) was twice greater than in hip flexors (–7 %). Interestingly, m. rectus femoris did not display any CSA reduction, while all three heads of m. vastus femoris showed a reduction of approximately 16%. The total CSA reduction in the unloaded limb was assumed to be due mostly to the CSA reduction in m. soleus (–17 %) and m. gastrocnemius (–26 %). Berg et al. [9] have observed that the isometric MVC and concentric forces of hip extensors were reduced by 25–30 % after bed rest for 42 days, while the CSA decreased only by 14 %; and maximal EMG activity, by 19 %.

Greater changes in muscle strength than in CSA suggest changes in internal properties of motor units, their recruitment, or neural drive. The last assumption is supported by a lower electromechanical efficiency, which is evident from the finding that higher EMG activity (+44 %) is involved in generating the same isometric force (100 Nm) after 6-week bed rest [9, 58]. Therefore, changes in muscle activation may substantially affect the operational ability of crew members upon landing after exposure to microgravity.

Here were report the changes observed in the maximal joint torques of several muscle groups and the muscle work capacity of nine crew members after Mir missions 213.0 ± 30.5 days and five visiting crew members after ISS missions of 7–10 days.
A unique feature of this study is that changes in contractile properties are directly compared for spaceflights of different durations and muscular alterations are considered in the context of using or not using PT during a spaceflight.

The objective of the study was to quantitatively estimate the changes in contractile functions and work capacity of muscles in cosmonauts after short- and long-term spaceflights by using isokinetic dynamometry during voluntary contractions. In the current study, we report changes in the strength skeletal muscle strength, and endurance (performance) in nine crewmembers missions of 213 days to the MIR and in five crewmembers missions of 10 days to the ISS. We assumed that the large changes will be observed after a long-term flights and a greater degree in of extensors muscles.

METHODS

All experimental procedures complied with the Declaration of Helsinki (1975) regarding the rights of human subjects involved in biomedical research. The study was approved by the Biomedical Ethics Committee at the Institute of Biomedical Problems (Russian Academy of Sciences) and Yu.A. Gagarin Cosmonauts Training Centre (Star City, Moscow).

Subjects

Two groups of male cosmonauts participated in the study. Group 1 (n = 9; 45.1 ± 2.0 years, 176.0 ± 2.3 cm, 79.9 ± 2.0 kg) included prime crew members from long-term missions (209.8 ± 30.5 days) to the Mir space station; group 2 (n = 5; 37.8 ± 3.7 years, 175.8 ± 1.7 cm, 72.8 ± 2.8 kg) included visiting crew members from short missions (9.4 ± 0.2 days) to the ISS. All crew members were informed about the goals and methods of the study of muscle contractile functions, the study procedures, risks, and study significance, and gave their written informed consent to voluntary participation in the study as subjects.

The cosmonauts did not do PT during short missions and followed a standard Russian PT program during long-term spaceflights [17, 61].

Testing Procedure

Torques of extensor and flexor muscles of the back, knee, and ankle were measured during voluntary movements of back, knee, and ankle flexion and extension. All testing was conducted on the right limbs. Peak torques and joint angle at peak torque of various muscles were measured with a LIDO® Active Multi-Joint Isokinetic Rehabilitation System, Loredan Biomedical (USA) [50], which was modified to measure the maximal joint torque during concentric muscle contractions of more than 400 Nm.

The protocol and procedures of testing muscle functions with a LIDO® system were explained to the subjects 30 ± 5 days before the spaceflight.

A subject sat comfortably on the special universal table of a LIDO® isokinetic dynamometer. The LIDO® dynamometer was calibrated externally and internally (electronically) before each test session, and a gravity correction procedure was performed to eliminate the effect of the limb.
weight on joint torque measurements. The subjects familiarized themselves with each angular test velocity by performing three to five movements, from which the maximum value from either of the two pre-flight baseline sessions was selected. Data were collected after 2-3 min rest.

Each subject was instructed to exert maximal effort in only one direction and in every movement when performing a test; no verbal instruction was provided during testing.

Three protocols were employed in pre- and postflight testing for maximal voluntary joint torques produced by various muscles.

In Protocol 1, joint torques were measured during voluntary concentric movements with various angular velocities when flexing and extending back, knee, and ankle muscles.

In Protocol 2, joint torques were measured during voluntary eccentric movements with various angular velocities when flexing and extending back, knee, and ankle muscles.

In Protocol 3, repetitions voluntary concentric movements were assessed upon ankle extension at a velocity of 60 °/s⁻¹.

Each subject performed three movements at a given velocity in a given movement mode with at least 1 min rest between movements. Prior to isokinetic testing, crewmembers joint-specific warm-up procedures consisted of five submaximal repetitions and two to three maximal repetitions using the actual testing movements and speeds. After the warm-up, crewmember rested at least 2-3 min before collection began. Strength tests were performed such that crewmembers exerted a maximal effort in only one direction for each set of repetitions. Gravity correction was employed to remove the effect of limb and limb adapter weight from the torque measurement.

Muscle strength was measured as a peak joint torque produced in the total range of concentric (Fig. 1, upper panel) or eccentric (Fig. 1, middle panel) movements, and the highest value obtained in consecutive voluntary contractions for both flexor and extensor muscles was taken as a maximal joint torque.

Testing the flexors and extensors of the back of the subject was carried out in a sitting position and angle of the hip joint was ~ 130-140 ° and hip axis coincides with the axis of rotation of the recording device isokinetic dynamometer (Fig. 1, top panel). The range of motion in trunk flexion and extension was 75–130 ° at angular velocities of 30 and 75 °/s⁻¹.

Testing the extensor muscles and the hip flexors of the subject was carried out in a sitting position and angle of the knee joint was ~ 90 °, and the axis of the knee joint coincides with the axis of rotation of the recording device of the dynamometer. The range of motion in flexion and extension was 90–60 ° in tests for maximal joint torque during concentric movements and work capacity and 33–90 ° in tests for maximal joint torque during eccentric movements. Angular velocities of thigh muscle contractions were 30, 60, 120, and 180 °/s⁻¹ in concentric movements and 30, 60, 90, and 120 °/s⁻¹ in eccentric movements.
Testing muscles, the extensor and flexor of the foot is performed in the test position "kneeling" and the angle of the knee and ankle joint was ~ 90° and ankle joint axis coincides with the axis of rotation of the recording device dynamometer (Fig. 1, lower panel). The range of motion in ankle flexion and extension was ~ 25° in the case of maximal extension and 20° in the case of minimal flexion in both concentric and eccentric movements. Angular velocities of ankle muscle contractions were 60, 120, and 180°/s in concentric movements and 30, 60, 90, and 120°/s in eccentric movements.

After voluntary testing, the subjects proceeded with the fatigue test. Skeletal muscle endurance was defined as the total work generated during 25 repetitions of voluntary concentric knee extension at an angular velocity of 60°/s in cycles of 1-s contraction and 1-s relaxation (Fig. 1, lower panel). The angle between the thigh and shin was 90° in the starting position. Prior to performing local dosed muscle work, the subject was instructed "to exert maximal effort in every movement".

The degree of fatigue, or performance, was evaluated in terms of fatigue index (FI), which was calculated as a ratio of the maximal joint torque averaged over the five last contractions in a series of voluntary 25 repetitions concentric muscle contractions to the maximal joint torque averaged over the five first contractions [38].

The leading limb was examined in all testing procedures (excepting the trunk), if not medically contraindicated. Joint positions (configurations) and ranges of motion were recorded for each subject and reproduced upon testing on day 3 (± 1) after landing.

All subjects were instructed to abstain from food for 2 hours before testing, from caffeine for 4 hours before testing, and from exercise for 12 hours before testing.

Exercise In space

To preserve the muscle contractile properties in long-term space missions, cosmonauts used PT, which were mostly of a locomotor type and were performed for 1.5–2 hours. Four-day microcycles, each including 3 days with PT and 1 day of rest, were followed in the PT program [17, 61].

A treadmill and a cycle ergometer were the main PT tools, training the cardiovascular and respiratory systems [21, 41]. The treadmill device could be used in a passive (subject driven) or active (motorized) mode of operation, which was selected by the crewmember during each exercise session. Crewmembers used a subject-loading device to fix themselves to the treadmill, which provided varying levels of loading relative to body weight (typical load was ~ 70 % of body weight) during use. In this way, the crewmembers could complete running or walking exercise while partially loaded. The cycle ergometer provided a load of 50–225 W at a pedaling rate of 40–80 rpm. The crewmembers also had access to bungee cords, which they could use to provide resistance-type exercise for various muscle groups.

Calculations and statistical analysis.
The effect of spaceflight on function [all isokinetic speeds and maximal voluntary contraction (MVC) angles] was analyzed using a one-way repeated-measures ANOVA for each variable. A significant time effect was interpreted using pairwise comparisons combined with the Bonferroni adjustment. For all strength measurements, data were collected at 500 Hz. From these data, peak torque, for any given measurement, was taken as the highest recorded value. Any record showing an artifact or torque spike was discarded and not used for analysis. During the maximal isokinetic contraction, the record with the greatest value was used. In addition, the angle-specific torque at 90° was recorded for all contractions. It should be noted that the muscular results from these experiments reflect those of space travel (which includes a heavy daily work schedule). Differences between preflight (baseline) and postflight parameters were checked for significance by the parametric Student t-test and were considered significant at p < 0.05.

RESULTS

Short-term Spaceflight

Our analysis of the functional changes in muscles showed that the maximal joint torques of flexor muscles were consistently lower than baseline in both concentric and eccentric voluntary movements at all angular velocities.

However, the decrease in maximal joint torque of hip extensors substantially varied (Fig. 2, upper panel), being the greatest in voluntary concentric movements in a low-velocity high-force mode at angular velocities of 30 and 60°/s\(^{-1}\) (by 16 and 13 %, respectively) and the lowest in high-velocity modes at velocities of 120 and 180°/s\(^{-1}\) (by 9 and 11 %, respectively). In the case of hip flexors, the maximal joint torque decreased insignificantly throughout the angular velocity range, by 3, 8, 11, and 6 % at angular velocities of 30, 60, 120, and 180°/s\(^{-1}\), respectively.

When analyzing the maximal joint torques produced by knee muscles during voluntary eccentric isokinetic movements, similar decreases (approximately 14 %) in contractile potential were observed at angular velocities of 60, 90, and 120°/s\(^{-1}\) and an insignificant increase (9 % on average) was only detected a low-velocity (high-frequency) regime.

Decreases in maximal joint torque of ankle extensors (Fig. 2, lower panel) were much the same (approximately 13 %) in eccentric isokinetic voluntary movements at angular velocities of 30, 90, and 120°/s\(^{-1}\). In the case of ankle flexors, the lowest changes (~ 6 %) were observed for low-velocity (high-force) movements (30°/s\(^{-1}\)).

A greater effect of spaceflights on muscle strength was observed for back muscles in both concentric and eccentric movements at all angular velocities. A decrease in strength of trunk extensors was maximal (33 %) in high-velocity movements and lower (27 %) in low-velocity (high-force) movements (Fig. 3). In the case of back flexors, a decrease in maximal joint torque was greater (16 %) at high velocities than at low velocities (high force) (approximately 6 %).

Figure 6 (upper panel) shows how the maximal joint torque of hip extensor muscles changed during rhythmic dynamic concentric movements (contractions) at a constant angular velocity of...
60°/s before and after a short-term space mission. A data analysis demonstrated that the maximal joint torque of knee extensor muscles generally decreased during rhythmic movements, but the kinetics of changes in torque did not significantly differ between pre- and postflight tests; i.e., work capacity of hip extensors, or their fatigue, did not significantly change after a spaceflight.

The FI averaged 0.90 ± 0.03 at baseline and remained much the same, 0.90 ± 0.04, after a spaceflight.

**Long-term Spaceflight**

An analysis of changes in the force–velocity parameters of knee flexors and extensors (Fig. 4, *upper panel*) showed, first, that the maximal joint torques of the muscles in eccentric movements were substantially higher than in concentric movements. Second, the maximal joint torque of thigh muscles decreased considerably in all crew members at all angular velocities both before and after a spaceflight according to isokinetic dynamometry data. The extensor muscles showed significant changes in both concentric and eccentric movement modes. The changes differed in extent between the modes, being greater in concentric than in eccentric movements. In the case of hip flexors, similar decreases in force properties (approximately 20 %) were observed at different angular velocities in both concentric and eccentric movements. In the case of hip extensors, such a pattern was not observed, and the changes varied. Substantial changes in maximal joint torque were detected during concentric movements in high-velocity (180 °/s; about 25 %) and high-force (60°/s; about 23 %) modes, while similar decreases in the parameter were seen at angular velocities of 120 °/s and 30 °/s.

A similar time course of changes in force–velocity properties was observed for ankle flexors and extensors (Fig. 5, *lower panel*). It should be noted that the maximal joint torques of ankle flexors and extensors changed to a greater extent than those of hip flexors and extensors. Greater changes were observed during movements in both concentric and low-velocity (30 °/s) high-force eccentric modes, especially in the latter. At higher velocities (120 °/s and 180 °/s), greater changes were detected in eccentric movements. Ankle flexors showed unidirectional changes, decreasing in maximal joint torque in both concentric and eccentric movements throughout the angular velocity range examined. The changes in maximal joint torque were somewhat greater in concentric voluntary movements.

An analysis of the changes in maximal joint torques produced by back flexors and extensors during eccentric and concentric movements (Fig. 5) showed, first, that the maximal joint torques produced by back flexors and extensors in eccentric contractions were significantly higher than in concentric contractions both before and after a spaceflight. Second, dissimilar muscle responses to unloading were observed during concentric and eccentric voluntary movements. Changes detected during low-velocity concentric contractions of back flexors were significantly lower than during eccentric movements. Back flexors showed opposite changes. At the same time, concentric voluntary movements at a greater angular velocity (75 °/s) revealed an opposite pattern. The greatest changes in flexors were observed during concentric movements compared with eccentric
ones, while back extensors displayed the greatest changes during eccentric movements compared with concentric ones.

The time course of changes in the force of knee extensor contractions was analyzed in crew members involved in long-term space missions. Tests for dynamic concentric rhythmic movements (contractions) at a constant angular velocity of 60 °/s−1 were performed before and after a spaceflight (Fig. 6, lower panel). The analysis showed a decrease in contraction force over 25 rhythmic contractions. In other words, the work capacity of knee extensors substantially decreased; i.e., fatigue of the muscular system increased after a spaceflight (p < 0.05).

The FI averaged 0.71 ± 0.04 at the baseline and increased to 0.81 ± 0.02 (p < 0.01) after a spaceflight.

DISCUSSION

The results of this study contribute to the literature describing the effects of spaceflight on strength various muscle. Our results supplement the literature data on the effects of short- and long-term spaceflights on the contractile properties of human muscles. A general trend observed in our study is that the maximal joint torques developed by lower-extremity muscles during concentric and eccentric isokinetic contractions decreased both after short- and long-term space missions.

A time course of functional changes arising in various muscle groups was inferred from the experimental findings. We showed that muscles respond to unloading in a nonlinear manner in humans exposed to microgravity, contractile properties decreasing to a greater extent in the flexor muscles that are involved in maintaining vertical posture under normal Earth’s gravity (1 g). Changes in extensor muscles were similar, but lower in extent. A direct strength comparison after a long-term spaceflight revealed certain differences for muscle groups involved in locomotion.

As demonstrated in earlier studies focusing on the characteristics of voluntary and electrically induced tetanic contractions of m. triceps surae, a short-term spaceflight causes a slight decrease in the forces of MVC (by ~ 9 %) and electrically evoked tetanic contractions (by ~ 8 %) and an increase in force deficiency (by 12 % on average) [36]. Long-term spaceflights lead to a substantial decrease in MVC force (by 22 %) and, what is of principal importance, muscle intrinsic force properties measured by the force of electrically evoked tetanic contractions (by 16 %), causing almost a twofold increase in force deficiency [35]. The findings directly indicate that a predominantly central mechanism determines a decrease in muscle contractile properties in a short-time spaceflight (in early exposure to microgravity), while a predominantly peripheral (intramuscular) mechanism comes into play at a next stage. The finding that force deficiency further increases after a long-term spaceflight indicates that the central mechanisms continue contributing to the decrease in muscle contractile properties.

A decrement in peripheral local muscle work capacity may be due to both a decrease in muscle strength because the total area under the work capacity curve depends on the force of contraction and a poorer ability to maintain (produce) high tension in muscle contraction, that is, a decrease in
endurance. The area under the curve decreased substantially for all regions of the contraction curve obtained for a test contraction after a spaceflight. The finding indicates that muscle work capacity was reduced not only because the force decreased, but also because endurance grew lower as well. It is infeasible to determine the specific contribution to work capacity for each particular factor because dynamic voluntary contractions were used to measure the work capacity, and these contractions provide an integral characteristic for both the contractile properties of the muscles involved (a peripheral factor) and their central nervous regulation (a central factor). Changes in the peripheral (contractile) component of the neuromuscular system cannot alone explain the decrease in muscle work capacity, although their contribution is major. A role is also played by alterations of the electrogenic component, including lower propagation velocities of action potentials in motoneuron terminals, neuromuscular synapses [36], and electrogenic membranes of muscle fibers [11, 12, 43]. As we have shown previously, more prolonged exposure to mechanical unloading of the muscular system leads to a relatively higher contribution of the electrogenic component to peripheral fatigue [29].

Greater changes in contractile properties have been observed by isokinetic dynamometry, wherein many muscles are involved in a given movement, as compared with tendon dynamometry [29, 35], wherein only one muscle is assessed. The finding suggests activation of antagonist muscles [16, 51, 54] and a role of efferent input to these muscles [52]. This input has a relatively low intensity, but seems to increase in microgravity, where support load as a factor that triggers important events in the locomotor system is absent, automatically suppressing (up to complete inhibition?) tonic activity and subsequently causing a number of physiological and structural secondary effects.

Another concept discussed in the spaceflight context is that mechanical unloading change the activation and pattern of recruited motor units, the change affecting the muscle output in movement tests. The simplest conditions for evaluating adaptation of the muscle contractile function are provided by isometric contractions, wherein the muscle length remains constant. However, the muscle length and loading may decrease or increase depending on the external conditions during movements in vivo. In spite of its complexity, the relationship between force and speed at a particular activation level is predictable for many skeletal muscles, given that the muscle architecture and movement mechanics are known. Although the function and work capacity of muscles change in microgravity, basic mechanisms generating muscle force are preserved. The force potential is somewhat higher when an activated muscle elongates at a zero speed. It should also be noted that the force decreases with the increasing contraction speed, and, vice versa, the maximal speed increases when a minimal load is imposed on contractile elements of the muscle.

Our findings show that greater unloading-induced changes in contractile functions occur in extensors compared with other muscles [3, 42] after a long-term space mission in spite of regular PT. The finding indicates that PT is not intense enough to preserve the muscle system [49, 66].
It follows that the contractile properties of a muscle depend on its activity history in addition to other factors. The cosmonaut training process was therefore analyzed, and the analysis showed that cyclic exercises were mostly employed in training crew members for long-term space missions. Such training seems insufficient for preserving the muscle function during a spaceflight. Hence, the training process should be planned with due regard to the functional potential of the neuromuscular system as a leading physiological system of the body.

The fact that muscle contractile functions decrease during space missions supports the idea that more efficient training programs are needed to protect skeletal muscles in long-term spaceflights. The majority of PT programs used during spaceflights utilize a treadmill and a cycle ergometer as main tools, providing mostly cardiovascular and respiratory training [21, 25, 41] and improving aerobic capacity, but not power properties of the muscle system. However, the programs have been found to be low efficient not only in maintaining muscle mass and functions, but also in regulating mineral turnover [55, 57]. As has been observed, the MVC force is already dramatically reduced (40 %) after 7-day unloading without PT and continues to decrease with increasing exposure duration [9, 23, 27, 29, 30, 34, 47]. Changes in neural drive may act as a MVC-limiting factor because muscle contractile properties have been found to decline greater than muscle mass, volume, or CSA in both model exposures (bed rest [37, 54]) and spaceflights [22, 47].

Power (resistance) training in 1-g conditions is known to increase muscle strength, muscle size, and neural drive [59]. Power training is therefore a promising means to alleviate muscle disadaptation in microgravity [63]. At any rate, observations have shown that, to maintain the mass and dynamic and isometric forces of hip and ankle extensors, it is enough to do resistance exercises every other day during a 14-day bed rest [7, 8] or every third day during a 21-day unilateral limb unloading (suspension) [60].

Therefore, the fact that muscle contractile functions decrease, especially in long-term spaceflights, supports the idea that muscle protection during long-term missions warrants a training program that includes high-intensity exercises to improve the power properties of muscles [24, 62, 66]. Power exercises seem promising for preventing muscle atrophy and weakness. Moreover, to make resistance training maximally efficient, a PT program should include both concentric and eccentric muscle contractions performed with a high intensity [7, 59, 65].

To summarize, our experimental analysis confirmed again that certain phenomena are seen after short- and long-term spaceflights, that is, exposure to real microgravity. We quantitatively described the postflight changes and assumed that at least two mechanisms are responsible for the decrease in muscle contractile functions, determining its two stages. A central mechanism mostly contributes to the decrease in contractile functions in early exposure to microgravity (short-time spaceflights), while a peripheral mechanism comes to play a major role at the second stage (long-term spaceflights).

Acknowledgments
I am grateful to the Mir and ISS crew members who agreed to take part in the study, which would be infeasible without their efforts; medical and engineering staff of Yu.A. Gagarin Cosmonauts Training Center at Star City, for their contribution to the organization of the study; and numerous unnamed specialists who helped to perform the study.

Figure 1

- Peak torque (extensor)
- Peak torque (flexor)
- Maximum isometric contraction
Angular velocity, deg/s$^{-1}$

Knee torque, N m

A

estensor

before

after

B

flexor

before

after
Figure 2

Back torque, Nm

Angular velocity, deg/s\(^{-1}\)

- **before**
- **after**

Flexion
- 30
- 75

Extension
- 30
- 75

Legend:
- **:** p < 0.05
- ***:** p < 0.01
Figure 3

**A**

Angular velocity, deg/s⁻¹

Knee torque, N·m

**B**

Estensor: before (△) after (●)

Flexor: before (●) after (○)

* indicates a significant difference before versus after.
Figure 4

![Graph showing back torque (Nm) before and after for flexion and extensor angular velocities (deg/s).](image)

- **Flexion**:
  - 30°: Before 100 Nm, After 200 Nm
  - 75°: Before 100 Nm, After 200 Nm

- **Extensor**:
  - 30°: Before 200 Nm, After 300 Nm
  - 75°: Before 200 Nm, After 300 Nm

*Significant difference marked with asterisk.*
Figure 5

- **Knee torque, N.m**
- **Fatigue index**
- **Number of contractions**

Comparison of knee torque and fatigue index before and after a certain number of contractions.

- Before: Solid circles
- After: Open circles

Legend:
- **before**
- **after**

Fatigue index values are shown as bars on the right side of the diagram:
- **before**: Dark bars
- **after**: Light bars

Significance levels are indicated by asterisks:* p < 0.05, ** p < 0.01.
